

1 **Appendix B: Documentation of key procedures for continuous ramped heating**

2
3 Details of the main analytical approach to Continuous Ramped Heating (CRH) can be
4 found in Idleman et al. (2018). In this document we explain important updates to our
5 analytical procedures and some caveats relevant to sample packaging and handling,
6 laser heating and temperature measurement, gas getting and monitoring, and data
7 collection and reduction.

9 **1. Sample packaging and handling**

10 Each apatite grain, after being picked and photographed, was packaged in a niobium
11 (Nb) tube with both ends closed – a standard approach for single-grain apatite (U-
12 Th)/He dating. The tube was then wrapped in a Nb foil envelope (Fig. B1A). The Nb
13 tubes we used for these experiments had an outside diameter of 0.4 mm and length of
14 0.7 mm. The foil envelopes were octagonal-to-circle shaped with a diameter of ~2 mm,
15 a size chosen to fit into the
16 indentation in a cylindrical
17 quartz glass sample holder
18 (Fig. B1B) and also to
19 completely contain the
20 measurement spot of the
21 optical pyrometer (~1.1 mm).
22 The holders fit into a sample
23 rack fitted with a linear

Figure. B1: Sample packaging.

24 actuator that allows up to 12 samples to be positioned under the laser beam (Fig. B1C).
25 Both the Nb tubes and foil envelopes were cleaned with 7% HNO₃ and degassed for 3
26 hours in a vacuum furnace at 600 °C before packaging. The overall goal of our
27 packaging strategy is to keep the sample packet as small as possible in order to allow
28 efficient and responsive laser heating (see following section) while still providing enough
29 packet surface area for accurate temperature measurement.

30

31 **2. Laser heating and temperature measurement**

32 The TAM samples were heated with a 30 watt 808 nm fiber-coupled diode laser, and
33 their temperatures were monitored using a BASF Exactus optical pyrometer positioned
34 coaxially with the laser beam path as part of a custom beam delivery system. The
35 pyrometer was recalibrated every 8-12 sample runs against a K-type thermocouple
36 embedded in a “dummy” sample packet in one of sample-rack positions. Temperature
37 regulation was achieved by modulating the laser power under closed-loop PID control
38 using a custom Labview program. For the TAM experiments we performed CRH
39 analysis using a heating rate of 30 °C/min. This rate was chosen to balance the
40 responsiveness of the temperature control system, the speed of ⁴He flow and pressure
41 equilibration within the extraction line, the efficiency of active gas cleanup, and the time
42 needed for the ⁴He signal to be integrated and recorded with sufficient precision.

43

44 **3. Gas gettering and monitoring**

45 CRH analysis involves continuous sample heating and measurement of released helium
46 gas under static conditions with the sample chamber open to the mass spectrometer.

47 The presence of other active gas components released from both the sample and the
48 extraction system will impact CRH analysis and therefore requires careful attention to
49 gettering and monitoring of these active gas contaminants. We have found that
50 hydrogen and nitrogen in particular can alter the effective ^4He sensitivity via pressure
51 scattering or possibly other source effects. For the TAM experiments we used two
52 SAES GP-50 getters operated at 20 and 200 °C in the extraction line for active gas
53 cleanup, as described by Idleman et al. (2018). Fortunately, laser heating is particularly
54 advantageous for CRH analysis, as the much smaller heated area relative to that
55 required for furnace-heating experiments helps to minimize the evolution of these active
56 gases. With our current laser heating setup, hydrogen and nitrogen co-evolved with ^4He
57 have the greatest impact on the effective ^4He sensitivity at temperatures where the
58 sample is almost completely degassed (i.e., > 850 °C) and can result in slight (~1-5%)
59 underestimations of the final ^4He abundance. This problem can be addressed effectively
60 by delaying the final measurement of the total ^4He beam intensity for ~3 minutes after
61 the termination of laser heating, allowing the partial pressures of the active gas
62 contaminants to fall to levels at which their suppression of the ^4He signal is trivial.

63

64 **4. Data collection and reduction**

65 The ^4He measurements were performed using a Pfeiffer Prisma Plus quadrupole mass
66 spectrometer fitted with a channel electron multiplier. The CRH measurements were
67 made in the static mode with the quadrupole fully open to the sample chamber.

68

69 The following sections highlight three key steps in our strategy for data collection and
70 reduction:

71

72 **Before heating.** We allowed at least two minutes of measurement of the dynamic
73 background in order to quantify the residual ^4He signal present before the extraction line
74 was valved off from its pumps. Once the pump valve was closed, we performed another
75 two to three minutes of measurement of what we found to be a linearly rising time-
76 dependent static ^4He blank, allowing us to calculate the blank contribution over the
77 course of the CRH experiment by extrapolation of these early measurements. In
78 practice, we have found that the magnitude of this time-dependent static blank far
79 exceeds the blank component contributed by sample heating, which in most
80 experiments is trivial.

81

82 **During heating.** Temperature recording was initiated shortly before the start of laser
83 heating. For the remainder of the experiment sample temperature and the ^4He beam
84 intensity were recorded at fixed intervals of 10 s and 10.2 s, respectively. During the first
85 10-20 seconds of the experiment the samples were heated rapidly to $\sim 160\text{-}170\text{ }^\circ\text{C}$
86 under manual control to bring them within the measurement range of the pyrometer.
87 After the sample temperature had stabilized for a few seconds control was passed to
88 the Labview software, which then proceeded with the programmed heating schedule
89 under closed-loop control. Heating and ^4He measurement continued until the sample
90 was completely outgassed, as indicated by either a stable ^4He beam intensity for at

91 least one minutes or, more often, a slightly decreasing signal owing to the buildup of
92 active gases.

93

94 **After heating.** After a sample was completely outgassed, we stopped temperature
95 recording and allow the system to cool for three minutes, during which we commonly
96 observed a 1-5% increase in the ^4He beam current until the beam current finally
97 stabilized. This increase typically coincided with an orders-of-magnitude drop in the m/e
98 2 and 28 beam intensities as the sources of coevolved H_2 and N_2 cooled and these
99 gases were gettered. We used the final ^4He beam intensity achieved after this cleanup
100 step for the age calculation. Once the ^4He beam had been measured we introduced a
101 calibrated aliquot of ^4He as a standard addition to establish the ^4He sensitivity of the
102 quadrupole.

103

104 After completion of a CRH experiment, temperature and ^4He abundance data were
105 synchronized by linear interpolation using the time stamps recorded with each
106 measurement. The accumulated ^4He blank (static blank) was calculated using the
107 previously determined accumulation rate and the heating duration. We then subtracted
108 the dynamic background and the time-dependent static blank from our measured ^4He
109 beam currents before calculating cumulative ^4He loss as a function of temperature (f),
110 and differentiation of the cumulative loss curve to obtain fractional loss (df/dT).
